Abstract

We develop a five-region version (Canada, an oil exporter, the United States, emerging Asia and Japan plus the euro area) of the Global Economy Model (GEM) encompassing production and trade of crude oil, and use it to study the international transmission mechanism of shocks that drive oil prices. In the presence of real rigidities that reduce the short- and medium-term responses of oil supply and demand, our simulations can account for large endogenous variations of oil prices with large effects on the terms of trade of oil-exporting versus oil-importing countries (in particular, emerging Asia), and result in significant wealth transfers between regions. This is especially true when we consider a sustained increase in productivity growth or a shift in production technology towards more capital- (and hence oil-) intensive goods in regions such as emerging Asia. In addition, we study the implications of higher taxes on gasoline that are used to reduce taxes on labor income, showing that such a policy could increase world productive capacity while being consistent with a reduction in oil consumption.

Keywords: Oil prices, world economy, DSGE models.

1 Introduction

Over the last few years, the persistent surge in oil prices in both the spot and futures market has represented perhaps the most striking challenge to the forecasting abilities of private and public institutions worldwide. Even as the average monthly spot price of oil increased from \$19 per barrel at end-2001 to \$43 at end-2004, market participants expected prices to decline over time. Technical factors did partially account for this phenomenon: for instance, the Organization of the Petroleum Exporting Countries (OPEC) established a price band mechanism whereby prices rising above a given ceiling would eventually trigger an adjustment in production, bringing about expectations of a future downward correction in prices.¹ However, during early 2005 — possibly exacerbated by the suspension of the price band mechanism — there was a substantial upward revision of near- and longer-term future contracts. Recently, with a June 2006 spot price of about \$71 per barrel and five-year forward contracts also hovering around that price, we are faced with several puzzles. What were the factors leading to the current situation? And furthermore, why did high oil prices fail to have more discernible effects on world growth and inflation?

As expected, demand and supply trends have been spotlighted as the main causes of these recent oil market developments. On the demand side, robust global growth supported by the rapid expansion in emerging Asia has been cited as a fundamental break with respect to past tendencies. With populations exceeding one billion each and sustained growth rates at double-digit levels, manufacturers and consumers in China and India have been importing energy at increasing rates. But the actual rate at which these economies are expanding seems to have surprised market participants significantly, as their observed growth rates have been significantly higher than consensus forecasts. In addition, solid growth in the United States and the recovery in Japan has led to significant upward revisions in global growth prospects and, in fact, global growth is expected to exceed four percent for the fourth year in a row (IMF (2006)).

Market participants have also revised their views about how quickly supply will respond to higher prices, given low levels of investment and the fact that big oil companies are finding it more difficult to replenish their reserves. Indeed, as it takes on average eleven years before an oil discovery is commercially available, it has not been surprising to some analysts that oil prices have soared when OPEC spare capacity has fallen to very low levels. The more controversial concern of the “peak oil theory” — the concept that the world has reached the natural limits of oil exploitation — is nowadays given more consideration than in the past. Given low levels of supply and geopolitical risks, the market has entered uncharted territory, making it more vulnerable to shocks and speculation.

This paper provides a preliminary assessment of these issues — and their relevance for the world macroeconomy — by developing an extended version of the Global Economy Model (GEM) developed at the International Monetary Fund (IMF) that explicitly encompasses consumption, production and trade in oil. The simulation model allows us to study developments in the world economy that have significant effects on oil prices, the international transmission mechanism through terms of trade fluctuations, and the related wealth transfers between oil-importing and oil-exporting regions. The remainder of this paper is organized in the following way. Section 2 presents some basic stylized facts in light of our

¹The price band mechanism set up by OPEC at its March 2000 meeting was such that OPEC basket prices above \$28 per barrel for 20 consecutive trading days or below \$22 per barrel for 10 consecutive trading days would result in production adjustments. However, during its January 2005 meeting, OPEC decided that market developments had rendered the band unrealistic, and temporarily suspended the mechanism.

introductory remarks. Section 3 provides a brief summary of the model while Section 4 discusses its calibration. Section 5 then uses the model to present some preliminary simulation results that we consider to be likely candidates in explaining the current run-up in oil prices, that we expect will extend into the foreseeable future. Specifically, we consider shocks that affect either the demand or supply for oil and discuss their implications for growth in different regions of the world. Section 6 suggests some policy responses to help ameliorate the upward climb in oil prices. In particular we study the implications of higher taxes on gasoline that are used to reduce taxes on labor income, showing that such a policy could increase world productive capacity while being consistent with a reduction in oil consumption. Last, the final section offers some concluding remarks about possible future extensions.

2 Oil and the world economy: some stylized facts

The purpose of this section is to present some basic facts on recent developments in the oil market and the world economy.

Oil prices There has been a persistent upward trend in oil prices over the last few years. Figure 1 depicts the evolution of the IMF’s World Economic Outlook (WEO) projections and the actual values of the average petroleum spot price (APSP). The APSP is the simple arithmetic average of the U.K. Brent, Dubai Fateh, and West Texas Intermediate spot prices, and the APSP projections are based on oil price future contracts traded on the New York Mercantile Exchange (NYMEX).

Focusing first on the Winter 2003 vintage in the top panel, we observe a short-term hump, owing to the events unfolding in Iraq. Afterward, oil prices were projected to converge to a much lower level, hovering around \$20 per barrel. There seemed to be an expectation that supply would accommodate market needs once the short-term disruptions were resolved. Moving on to the 2004 projections, a milder uptick in price expectations was accompanied by an upward revision in longer-term prices by about twenty percent relative to the previous projection, as shown in the bottom panel. Next, in 2005 there was both a large near- and longer-term revision to oil prices, owing to significant changes in the oil market. Notice in particular that the long end of the projected oil price curve increased by nearly 100 percent, likely caused by a disappointing supply response. Most recently, compared to the Winter 2003 projections, the longer-term oil price has been revised upwards by about 200 percent. In contrast with the three other curves, the Winter 2006 projections are almost constant going forward, primarily because of heightened concerns over the supply of oil.

Oil supply and demand Several mutually reinforcing developments have resulted in low levels of oil supply. The most prominent of these is that — including Iraq — OPEC spare capacity has bottomed out. This fact is highlighted in Figure 2, which shows quarterly figures for OPEC spare capacity as a percent of total supply, and the APSP. Notice the divergence between oil prices and spare capacity, which as of June 2006 is estimated at around 1.3 to 1.8 million barrels per day (EIA (2006)). At the same time, lagging investment in infrastructure and refinery construction, as well as the aforementioned fact that it takes on average eleven years before an oil discovery is ready for production, have further compounded supply-side rigidities. Markets have also been keen to note that big oil companies are finding it more difficult to replenish their reserves. Along with heightened geopolitical risks,

oil supply has become markedly binding, making it excessively vulnerable to even minor disruptions.

Probably the most important driver of world demand for oil is growth, in particular the rapid — and underestimated — expansion in emerging Asia. Table 1 underscores this point. It tabulates both the current year forecasts and actual real GDP growth rates from 2003 to 2005 for China and India. For both countries, the growth forecasts have been consistently lower than the realized rates. Moreover, solid growth in the United States and the recovery in Japan has led to significant upward revisions in global growth prospects. This is clearly conveyed in Figure 3, which shows the WEO projections for world real GDP growth in the top panel and the revisions relative to the Winter 2003 forecasts in the bottom one. In turn, Figure 4 emphasizes this point by focusing on the cumulative growth rates: the compounded effects of seemingly minor revisions can be quite large. To drive home this point, we also show the cumulative growth rates for the emerging Asian countries in Figure 5. Looking forward, global growth is expected to exceed four percent for the fourth year in a row (IMF (2006)).

Taking a more historical perspective, we note that there has been a gradual downward trend in oil intensity. As measured in kilograms per unit of PPP-adjusted GDP, Figure 6 shows declining oil intensities for selected countries and regions. Although after the 1970s the decline accelerated, the overall decrease in oil intensity has been protracted. As shown in both panels, advanced countries tend to have higher oil intensities. With populations exceeding one billion each and sustained growth rates near the double-digit range, manufacturers and consumers in China and India have been importing energy at ever-increasing rates. One key source of uncertainty is how this increasing shift toward higher oil intensity goods and inputs, combined with a high growth rate in a populous region, will affect future and — through forward-looking behavior — current oil market developments.

3 The theoretical framework of the model

This section provides a synthetic overview of our simulation model. The world economy consists of five country blocs ('regions'), divided in two groups. The oil-exporting regions consists of Canada and the group of oil-exporting countries (GOEC) which includes OPEC, Mexico, Norway and Russia.² The oil-importing group consists of the United States, emerging Asia³, and the bloc of remaining countries which includes Japan and the European Union. In each region, there are households, firms, and a government. The overall structure of the model is illustrated in Figure 7, and each sector is described in turn below.⁴

Each household consumes a non-tradable final good (C in Figure 7), and is the monopolistic supplier of a differentiated labor input (L) to all domestic firms. Some households have low monopoly power, are liquidity-constrained, and do not have access to capital markets. They finance their consumption exclusively through disposable labor incomes. The remain-

²This version of the model was built to originally include both energy and non-energy commodities. Therefore GOEC also includes other major commodity exporters such as Argentina, Brazil, Chile, South Africa, Australia and New Zealand.

³Indonesia is excluded and is part of the group of oil exporting countries.

⁴For an algebraic exposition of the model (excluding the treatment of the gasoline and oil sectors) we reader is referred to the Appendices of Faruquee, Laxton, Muir and Pesenti (2006a,b). A simplified variant encompassing both downstream and upstream intermediate goods is presented in Laxton and Pesenti (2003).

ing households own domestic firms and the domestic capital stock (K), which they rent to domestic firms. They also own two short-term nominal bonds, one denominated in domestic currency and issued by the region’s government, and another denominated in U.S. currency and issued in zero net supply worldwide. There are intermediation costs for national households transacting in the international bond market. Labor and physical capital are immobile internationally. The market for capital is competitive, and capital accumulation is subject to adjustment costs. In the labor market wage contracts are subject to nominal rigidities.

On the production side, there are three layers of production: final goods, downstream intermediate goods (such as semi-finished products), and upstream intermediate goods (such as refined oil products in our setting, and more generally commodities and raw materials).

Perfectly competitive firms produce two final goods — a consumption good (A) and an investment good (E). The final goods are not traded internationally. Both the demand for the consumption good and the investment good is split between private agents (C and I respectively) and the public sector (G_C and G_I respectively). The two final goods are produced by using downstream intermediate goods as inputs.

There are three downstream intermediate goods: refined petroleum products such as gasoline for transportation and fuel used for heating (‘gasoline’ for short, or GAS), other non-traded goods and services (N), and internationally traded goods (T). Domestic tradables used by domestic firms are denoted Q , imports from all other country blocs are denoted M . To model realistic dynamics of trade volumes, we assume that imports are subject to short-term adjustment costs that temporarily lower the response of import demand to changes in relative prices. Intermediate goods are differentiated, with each variety produced by a single firm under conditions of monopolistic competition worldwide. The prices of intermediate goods are subject to adjustment costs (nominal price rigidities). Gasoline, nontraded and traded intermediate goods are all produced with domestic labor inputs, domestic capital and oil. Oil can be imported (MO) or produced domestically (QO); in both cases the use of oil in production is subject to short-term adjustment costs.

In our model, refined oil (‘oil’ for short) is the only tradable upstream intermediate good (TO). It is produced with capital, labor, and natural resources ($LAND$). As with other intermediate goods, oil producers have market power that can change over time. Different from intermediate goods prices or labor wages, oil prices are not subject to nominal rigidities. However, there are real rigidities in the supply of oil that result in very low short-term responses of oil production to changes in demand. As a caveat, the fact that oil is assumed not to be a storable commodity whose price is linked to the rate of return on other assets implies that its price is determined entirely on its use value. Since the model does not include oil inventories, oil prices may respond too strongly to temporary shocks. With this in mind, it should be emphasized that the model is not meant to explain short-run variations in oil prices due to market disruption: rather, it has been designed to explain the interaction of oil prices and the world economy over the medium term.

Finally, the government purchases the two final goods as well as nontradable services G_N . As treasury, the government finances the excess of its expenditures over net taxes by borrowing from the domestic private sector. In the long run the government targets a given ratio of public debt to income, adjusting the tax rate on labor incomes as appropriate. As central bank, the government manages the national short-term nominal interest rate. Monetary policy is specified in terms of a credible commitment to an interest rate rule that targets inflation.⁵

⁵Another version of the interest rate rule can limit the flexibility of the nominal exchange rate against

4 Calibration

This section describes the calibration of GEM, with particular attention to the oil and gasoline sectors. In this paper the calibration builds upon work already presented in Faruquee, Laxton, Muir and Pesenti (FLMP, 2006a,b). However, there are some notable differences in terms of the composition of regions and the addition of the oil and gasoline sectors. The notation adopted in this section and in Tables 2 through 10 is usually self-explanatory: for a fuller presentation the reader is referred to the Appendices of FLMP (2006 a,b).

Table 2 includes the parameters relevant for the consumers' and firms' optimization problems. As mentioned above, in each region there are two types of consumers — liquidity-constrained, low-monopoly power households and forward-looking, high-monopoly power households. Their shares differ across regions, with liquidity-constrained consumers being as low as 15 percent of households in the United States, to 50 percent in emerging Asia. Both types of consumers have similar preferences, with a high elasticity of intertemporal substitution ($1/\sigma$) of 5, coupled with a high level of habit persistence in consumption (b_c) of 0.92. This parameterization yields very sluggish and consumption behavior in the short-run, with a hump-shaped response that is flexible in the long run. Conversely for labor we have a low Frisch elasticity of labour supply ($1/\zeta$) of 0.2 coupled with habit persistence in leisure (b_L) of 0.75.

Table 3 contains the calibration of the production side of the model. The tradable and nontradable sectors are calibrated in much the same manner as FLMP (2006a), although the substitutability among factors is more inelastic, in line with recent work on Canada (Perrier (2005)) and the United States (Gosselin and Lalonde (2005)). The elasticity of substitution among factors used in oil production (ξ_O) is 0.6, but it is 0.7 in gasoline production (ξ_{GAS}). The higher degree of inelasticity in oil production reflects some of the long-term costs in switching production technology, whereas the higher value in gasoline production reflects the fact that there are several methods of varying efficiency (and hence capital and labour intensity) to obtain gasoline from oil. In sum, while the long-run elasticities in the oil-related sectors are low, they may still not provide realistic price responses in the short run. The latter require strong short-run real rigidities to significantly lower short-term elasticities toward near-Leontief levels, as will be described below.

The regions are differentiated from one another by their economic size, the composition of their domestic economies, and their trade patterns (see Tables 5 and 6). These data are mostly derived from the National Income and Production Accounts of the countries of each region, and then mapped into the corresponding bias parameters in the production functions for tradables, nontradables, oil and gasoline (Table 3) and the demand functions for final goods (consumption and investment) and intermediate goods (domestically produced and imported tradables, nontradables, gasoline and oil, Tables 4 and 3). The role played by differences in technology is immediately evident when we take into account factor incomes in the oil sector (Table 6). Some oil-exporting countries (GOEC) have the least capital-intensive technology, but other oil-exporting countries (Canada in our setup) have a relatively capital-intensive technology, meant to capture realistic features of the oil extraction process in the country (i.e. the Athabasca tar sands or the offshore oil-rigs of Hibernia).

Figures 8 and 9 illustrate our calibration of the world trade flows for all goods and for oil,

the U.S. dollar, which will be used in future simulation exercises for the emerging Asia bloc.

respectively.⁶ The aggregate import to GDP ratios reflect the levels of imports in 2003 in the five regions, whereas the aggregate export to GDP ratios are those necessary to support the net foreign asset to GDP ratios we have chosen (Table 5). The decomposition of aggregate trade flows into bilateral trade flows are also based on 2003 trading patterns found in the IMF’s Direction of Trade Statistics and UN’s COMTRADE database of commodity-based trade flows.

For aggregate trade, exports and imports to GDP are 74.1 percent in Canada, 48.0 percent in GOEC, 27.9 percent in the U.S., 52.6 percent in emerging Asia and only 17.8 percent in the remaining countries. The higher trade is as a percent of GDP, the more likely an economy will be affected strongly by foreign shocks. Canada is very open, as is emerging Asia, while the United States, the European Union and Japan (part of the remaining countries’ bloc) are much more insulated from foreign disturbances. However, this is not necessarily the case in the oil market. Here, not only does the degree of openness matter, but the direction of trade as well. The net exporters are Canada at 3.7 percent of GDP and GOEC at 8.1 percent of GDP, while the other regions are net importers at 1.4 percent of GDP for the U.S., 1.9 percent of GDP for emerging Asia and 0.4 percent of GDP for remaining countries. Additionally, the group of oil-exporting countries has the largest amount of its GDP coming from oil production (12.0 percent).

For tradable goods across all regions, imported goods are fairly substitutable with their domestically produced counterparts (μ_A and $\mu_E = 2.5$). Imports of tradable goods can originate from different export countries, and the elasticities of substitution between alternative exporters (ρ_A and ρ_E) are equal to 1.5. By contrast, there is a very low elasticity of substitution between tradable and nontradable goods in all regions (ϵ_A and $\epsilon_E = 0.5$), and a very high elasticities of substitution between domestic and imported oil (μ_{OT} , μ_{ON} and $\mu_{OGAS} = 10$). For imported oil, there is less preference as to the region of origin ($\rho_O = 3.0$).

As in all previous work on GEM, for prices in the monopolistically competitive tradable and nontradable sectors the calibration of markups follows Martins *et al.* (1996), and for wages follows Jean and Nicoletti (2002) (see Table 8). For oil, we have assumed almost no markup in the oil sector for any region, with the exception of the group of exporting countries, which has a markup of 476 percent. It is estimated that the cost of oil production for OPEC countries is somewhere around \$2 to \$5 per barrel, while for a country like Canada it is closer to \$25. So, for any given oil price in the world market that we are considering in the paper, the group of the oil-exporting countries has the largest markup to sustain the price of oil and guarantee production in the other regions where production cost are much higher. For gasoline, the markup is 16 percent in Canada and Japan and the European Union (i.e. the remaining countries) and 17 percent everywhere else. This excludes government taxes on gasoline, which we set for illustrative purposes at 30 percent in Canada and the remaining countries bloc and 15 percent elsewhere (including the United States).

The dynamics of the model are further affected by nominal rigidities and real adjustment costs, as found in Table 9. Nominal rigidities in prices and real rigidities in investment and trade are calibrated to match moments of other models such as ToTEM for Canada (Murchison and Rennison (2006)), MUSE for the United States (Gosselin and Lalonde (2005)), previous work on GEM for the United States (Julliard *et al.* (2006)), and the new Area-Wide Model (Coenen *et al.* (2005)) and Smets and Wouters (2005) for the European Union.

⁶The bias parameters associated with the import demand CES aggregators can be found in Table 7.

The most important real rigidities for this paper are those associated with the energy sectors. On the supply side there are adjustment costs associated with changes in capital (ϕ_{KO} and ϕ_{KGAS}) and labor (ϕ_{LO} and ϕ_{LGAS}) in the production of oil and gasoline. On the demand side, there are adjustment costs associated with changes in the use of oil in the production of intermediate tradables, nontradables and gasoline (ϕ_{OT} , ϕ_{ON} and ϕ_{OGAS} respectively), and in the use of gasoline as a component of the final consumption bundle (ϕ_{GAS}). These real rigidities are all modeled as quadratic adjustment costs following the Rotemberg (1982) formulation. The parameters associated with the adjustment costs are set at 300, a value high enough to generate considerably muted short-term price responses of supply and demand for gasoline and oil to changes in fundamentals.⁷ This implies that, for any shock affecting the demand or supply of oil, oil prices move rapidly but volumes are inert for around 5 to 10 years.

The last key element in the dynamics of the model is the conduct of monetary policy, found in Table 10. For simplicity, all regions are assumed to be inflation targeters that follow an inflation-forecast-based (IFB) rule.⁸ In order to hit a target of 2 percent (2.5 percent in the U.S.) for core consumer price inflation four to six quarters in the future, the change in the interest rate must be twice as large as the deviation of core inflation from its target level.⁹

5 Why oil prices have increased: some illustrative experiments

This section starts by presenting some simulation results showing the importance of rigidities that limit the short-run responses of demand and supply for crude oil, and what implications this has for how oil prices respond to productivity shocks. While we show that in the presence of these rigidities an upward shift in productivity growth can result in the combination of high oil prices and robust global growth, the results are preliminary and will be extended later in the context of a formal analysis of the role of demand and supply shocks over the last 3 years. Next, we investigate the implications of higher oil reserves in the future and we analyze the effects of a pure supply-induced shock that increases oil prices through raising the market power of oil producers. In the last experiment we illustrate how the model can be used to assess major risks to the future demand for crude oil that are the result of uncertainty about future levels of oil intensity and real incomes in emerging Asia. Taken in combination, we are confident that the three experiments provide the explanation for the increase in the general level of the price of oil over the past several years.¹⁰ In particular,

⁷However, Canada is assumed to have stronger real rigidities in oil production (because of the difficulty of exploiting the Athabasca tar sands) while the group of oil exporting countries is assumed to have weaker real rigidities (because of the ease with which the abundant near-surface oil in the Middle East can be extracted).

⁸As mentioned above, in future versions of this work emerging Asia will be alternatively assumed to pursue a fixed exchange rate target *vis-à-vis* the United States.

⁹Core inflation in this model excludes the effect of gasoline prices on the consumption price deflator (a proxy for the CPI excluding food and energy or some similar measure).

¹⁰It is understood that the current level of oil prices is not totally explicable in the context of these three shocks, as some of the volatility in the price of oil has nothing to do with the fundamentals of the market. Rather, they are linked to the perceived political risks attached to the various players (such as the Middle East or sub-Saharan African countries). Quantification of such uncertainty, by definition, has no role in a structural model such as the GEM.

the role of productivity and the types of oil usage that we see in emerging Asia have been a key driver as of late, and will continue to be so going forward.

5.1 Higher productivity growth in oil-importing regions

To investigate the effects of rising global demand for oil we consider a positive shock in the oil-importing regions (the United States, emerging Asia, the remaining countries bloc) that raises productivity growth in both the tradables and nontradables sectors by one percentage point for 20 years. However, before presenting the short- and medium-term implications of higher productivity growth on oil prices and the world economy, we develop a benchmark scenario where all rigidities that limit the short-run and medium-term responses of the demand and supply of oil to changes in the price of oil are turned off. The comparison of our simulation results with the benchmark scenario is meant to emphasize two elements: on the supply side, we introduce significant real rigidities in the attempt to mirror the effects of severe capacity constraints in the energy sector, as well as the multi-year delay between oil discoveries and their commercial availability; on the demand side, these rigidities capture the fact that it takes years to change the fuel efficiency of the stock of motor vehicles or to replace the stock of technology that is used for heating and cooling. Needless to say, because of these rigidities both the demand and supply for crude oil will be extremely inelastic in the short run, requiring large movements in crude oil prices to clear the energy market. Later, after showing the implications of rigidities, we will also consider another case where oil reserves increase in response to higher oil prices.

5.1.1 Responses without real rigidities in the energy sector

Figures 10 to 12 report results where all the rigidities that affect the short-run demand and supply for oil and gasoline are set to zero. The oil-importing regions obviously benefit from higher levels of productivity in their own region, but the increase in oil prices over time also results in a favorable terms-of-trade shock for regions that are net exporters of oil (Canada and the group of oil-exporting countries (GOEC)) and a negative terms of trade shock for the regions that are net importers of oil. To interpret these results it is important to recall that, in the baseline, net exports of oil in Canada and the group of oil-exporting countries are equal to 3.6 and 8.1 percent of GDP, while emerging Asia, the United States and the remaining countries bloc are assumed to be net importers of oil, with oil trade balances equal to -1.9, -1.4, -0.4 percent of GDP, respectively.

In this purely illustrative case, the price of oil trends upward in tandem with the increase in the demand for oil, reflecting the assumption that there are diminishing returns in the production of oil because of the existence of a fixed factor (land). For example, for the group of oil-exporting countries, Figure 12 shows that oil prices barely move in the short run, but then rise gradually over time reaching a level that is about 15 percent higher after 15 years. This results in an expansion in oil production of only 1.5 percent in the group of oil-producing countries. It is important to emphasize that in this simulation we are assuming that there are no new discoveries of oil and that production can only be increased by adding more capital and labor based on existing reserves. Again, it is worth emphasizing that this experiment is based on purely artificial assumptions to be relaxed later.

The gradual rise in oil prices results in an improvement in the oil balance for Canada and the GOEC and a deterioration in the regions that import oil. The rise in the price of oil results in an upward trend in the relative price of gasoline. While monetary policy

is successful at keeping core inflation close to the assumed target, headline inflation is systematically higher than in the baseline.

The dynamics for consumption, investment and GDP are relatively straightforward. In those regions that experience higher productivity growth investment trends upwards until the capital stock in these economies adjust to its new higher level. In the medium term, high investment rates in these regions crowd out investment in the oil-exporting countries as the rates of return on non-oil investment projects is significantly lower than the marginal product of capital in the regions that have experienced the productivity gains. However, these effects are eventually offset by higher rates of return in the oil sectors in these economies and aggregate investment rises above baseline. Consumption rises by more than GDP in the oil-exporting regions and by less than GDP in the oil-importing regions, which simply reflects the terms-of-trade improvement that the latter experiences.

There are two major forces that require the real effective exchange rates for the oil-importing regions to depreciate in the long run. The first is a result of the improvement in the terms of trade in the oil-exporting regions and the second reflects the assumption that higher growth in the oil-importing regions stems from higher levels of productivity in both the tradables and nontradables sector. In this case, equal-sized productivity shocks in both the nontradables and tradables sectors lead to a depreciation of the exchange rate in the long run, while the standard Balassa-Samuelson effect — predicting a real exchange rate appreciation in the long run — relies on productivity growth in the tradables sector exceeding that of the nontradables sector.

Perhaps surprisingly for the United States, the real exchange rate appreciates in the short run. This reflects the fact that this region must absorb most of the depreciation in emerging Asia and the remaining countries bloc, both blocs being characterized by strong trade linkages with the United States. This is also the source of the short-run fall in U.S. net foreign liabilities measured as a ratio of nominal GDP, even as the trade balance worsens. In the very long run the desired stock of U.S. net foreign liabilities is actually higher than in the baseline, a fact that contributes to generate pressure toward a long-run depreciation. The latter is needed to generate a trade surplus that finances the higher interest burden on the larger stock of net foreign liabilities.

5.1.2 Responses with real rigidities in the energy sector

Figures 13 to 15 report the effects of the same productivity shock discussed above, except in this case the rigidities that limit the short-run oil supply and oil demand responses are fully operational in the simulation exercises. Oil prices now jump up on impact, decline over the first year, before rising steadily over time. A comparison of Figures 12 and 15 show that oil prices are substantially higher over the medium term, reflecting the sluggish response of the supply of crude oil. As can be seen in the figures, higher oil prices greatly magnify the near-term and medium-term effects of the terms-of-trade effects and increase the magnitude of the wealth transfer between regions that import oil and regions that export oil.

While this has significant effects on the short-run dynamics, the basic macro dynamics presented earlier remain in place. Although the magnitudes of the real exchange rate responses are different than in the case with no rigidities, they follow the same basic pattern. In spite of the large oil price increase, the stance of monetary policy is adjusted in all regions to keep core inflation close to the target. This requires an increase in nominal interest rates that is larger than the increase in headline inflation, because higher productivity growth

increases the marginal product of capital and implicitly shifts the neutral policy rate.¹¹

While we have not performed a detailed accounting of the role of demand shocks behind the hike in oil prices over the last three years, this illustrative scenario shows that it is possible in principle to account broadly for the combination of high oil prices and robust global growth, once the role of stronger fundamentals driving underlying productivity growth is appropriately considered.¹²

5.2 Expectation of greater availability of oil reserves in the future

The previous results are likely to overestimate the effects of persistent productivity growth shocks on oil prices in the future, because they assume that the available level of reserves is fixed and will not increase in response to higher oil prices. Our modelling strategy in fact treats available oil reserves as an exogenous variable, without attempting to model new oil discoveries.¹³ In addition to finding new oil fields, there are two additional reasons why available reserves could increase in response to higher oil prices. First, the latter create incentives to develop new technology to produce crude oil from existing fields. Second, when access to oil fields has been restricted by governments, they may choose to reduce these restrictions either to raise the levels of revenue or because of concerns about energy security.

Figures 16 to 18 report results where we assume a gradual increase in available reserves in the oil-exporting regions (Canada and the group of oil-exporting countries) starting in the sixth year of the simulation. As can be seen in Figure 18, this results in an increase in oil production after 15 years by about 6 percent in Canada and by about 8 percent in the group of oil exporters. Reflecting the larger supply, there is a downward shift in oil prices by about 10 percent from the sixth year onward. This expected improvement in the terms of trade for oil-importing regions raises consumption, investment and GDP in the short run and reduces consumption in the oil-exporting regions. In the short run investment also rises in the oil-exporting countries, as the oil extraction process in the future is expected to require additional levels of capital.

The pattern of oil prices clearly show a potential weakness of the model, which assumes that oil is not a storable commodity but derives its value only from its use in production and consumption. Extending the model to allow for oil inventories would obviously smooth out the decline in oil prices observed after the sixth year. Also, allowing for trade in oil stocks would create an arbitrage condition that would link changes in oil prices to the rates of return on other assets. Unfortunately, both of these assumptions would greatly complicate the structure of the model.

¹¹While we do not have a neutral policy rate in the reaction function, the latter is specified in a way that allows the real interest rate to depart from its long-run equilibrium value when there are shocks that change the marginal product of capital over long periods of time. This, of course, is necessary condition to keep core inflation close to the target.

¹²Once the calibration of the model has been finalized, we plan to develop estimates of demand and supply shocks that can account for high oil prices and the pattern of growth and savings behavior observed over the last few years — for a similar exercise that ignored the role of oil prices see FLMP (2006a).

¹³In a future versions we may add an option where available oil reserves will behave as quasi-fixed factor that responds with very long lags to changes in oil prices.

5.3 Supply-induced oil price hike

Figures 19 to 21 report the results for a supply shock that raises the price of oil by about 50 percent after 10 quarters and by about one half as much after 15 years. Interestingly, because the demand for oil is very inelastic in the short run, the downward time profile for oil prices is consistent with a markup over marginal producer costs that rises gradually over time.

The increase in the terms of trade in favor of the oil-exporting regions leads to an increase in consumption in the short run. However, to mimic the qualitative behavior of actual current account surpluses in the recent past, we assume that this change is accompanied by an upward shift in the desired net foreign asset positions of all oil-exporting regions. This limits the rise of consumption over the medium term, but allows consumption to be permanently higher in the long run.

Higher wealth also leads to a fall in labor supply, as it results in an increase in time devoted to leisure. For the group of oil exporters, since oil is such an important part of their economy (12 percent of production), real GDP actually falls permanently (by about 2.5 percent) as export volumes drop. This effect may be offset partially by special circumstances in the labor market in these economies — for instance, because their economies depend heavily on migrant labor.¹⁴ Therefore, we assume a shift in the labor supply function that allows a slight increase in labor effort in the group of oil-exporting countries rather than allowing it to fall over time. The oil-importing regions are clearly worse off, as they face a negative terms-of-trade shock that increases the cost of producing goods and services, which over time results in a decline in investment and lower levels of productive capacity.

5.4 Increase in the demand for oil in emerging Asia

Long-term projections of the demand for oil depend critically on assumptions about the future usage of motor vehicles in emerging Asia. This should not be surprising, given its enormous population as well as the potential uncertainty associated with the speed at which its real per capita income is likely to bridge the gap with the OECD countries. But studies that have focused on the implications of this uncertainty have usually taken energy prices as given and assumed that the supply of oil will be sufficient to smoothly accommodate variations in its demand — see for example IMF (2005b). To consider the implications of permanent shocks to the future demand for oil in emerging Asia, we first consider a scenario in which the increased demand for oil is the result of two factors: a taste shift that raises consumers' demand for gasoline, and a technology shift that increases the amount of oil needed to produce tradables and nontradables. The shock is phased in slowly over time, and raises the real level of oil consumption by roughly 2.5 percent of GDP by the fifteen year of the simulation. We then consider an alternative scenario that combines the increase of intensity in oil usage with higher productivity growth in emerging Asia.

Figures 22 to 24 report the results. An increase in demand for gasoline in emerging Asia raises oil prices and shifts the terms of trade in favor of the oil-exporting regions (Canada and the group of oil-exporting countries) and against the oil-importing regions (United States, emerging Asia and the remaining countries bloc). As a result consumption increases in the regions that are net exporters of oil and eventually declines in the regions that are net importers.

¹⁴This is particularly true of the OPEC countries. For example, in 2003, 79 percent of workers in Saudi Arabia were non-Saudi nationals.

In terms of quantitative magnitudes, crude oil prices rise by about 10 percent on impact, decline over the first year and then trend upwards over time reaching a peak that is around 25 percent higher than baseline. Again, the profile for oil prices reflects very low short-run elasticities of supply and demand for crude oil, which means that oil prices have to bear all of the burden of adjustment in the short run. The effects on oil trade balances are much larger in the short run for the GOEC and Canada relative to the baseline (equal to 8.1 and 3.6 percent of GDP, respectively). The negative effects on the oil trade balance in emerging Asia builds up over time and reaches about 5 percentage points of GDP after about 15 years.

This analysis has assumed that the shock was a pure shift in tastes toward consumption of transportation services that use gasoline intensively. Obviously, the interaction of higher growth combined with increased intensity of oil usage could have much more important implications for the demand for oil and the world economy. Conventional econometric estimates of the demand for motor vehicles suggest that these goods are luxury items whose consumption shares expand with higher levels of wealth and real income. To understand the importance of this interaction, we consider a scenario where productivity growth is higher in emerging Asia and that this is associated with an increase in the intensity of oil usage. Figures 25 to 27 report the results for the oil-intensity shock considered above, along with an increase in productivity growth in both the tradables and nontradables sector. The effects of the oil-intensity shock are amplified by the increase in productivity, and vice-versa — the results of the two shocks are closer to multiplicative, not additive. We see the world price of oil increasing almost 20 percent on impact (twice that of the oil demand shock alone) and 60 percent in the long run.

6 Some potential policy responses

Given the long-run nature (i.e. usually a minimum of 15 years) of the scenarios offered above, we think it is appropriate to provide some normative suggestions as to how policymakers (particularly the regions' governments) can help reduce dependence on oil, and reduce the negative impacts that still-increasing and high oil prices will have on future world output growth. To use our model to its potential we focus on concrete policy measures, not regulatory measures or legal restrictions on fuel usage in the automobile sector or industry, since these can be hard to quantify in a model-consistent fashion. While several policy experiments could be carried out with our model involving both (or either) firms and individuals, we demonstrate below that the governments can use a global hike in tax rates on gasoline, in tandem with a reduction in taxes on labor income to achieve a notable reduction in oil prices and use of oil.

6.1 A global increase in gasoline tax rates

Having explored some scenarios for oil prices and the world economy, we now consider a policy measure that would encourage conservation and reduce the world price of oil. We focus on the effects of a 25 percentage point increase in gasoline tax rates in all regions of the world. In each region it is assumed that the additional tax revenue is used to reduce distortionary taxes on labor income. As a result productive capacity increases, with positive effects on aggregate employment and investment. The results are reported in Figures 28 to 30.

The tax hike on gasoline eventually results in a substitution away from consumption of energy, but this is a very long and slow process given the low short-run elasticities of demand for oil. Oil prices decline by almost five percent, which results in a wealth transfer from oil-exporting regions to oil-importing regions. This decline in prices results in a reduction in the oil trade balance in the group of oil-producing countries that is about twice the effect for Canada, reflecting differences in the initial oil trade balances. The reduction in labor tax rates raises the aggregate real wage and results in higher investment and GDP in the oil-importing countries, but this effect is also quite significant in Canada, where the expansion in employment in the non-oil sector outweighs the decline in employment in the oil sector.

Consumption in the oil-importing (oil-exporting) regions increases (decreases) because lower oil prices represent a positive terms of trade shock and a wealth transfer from oil-exporting regions to oil-importing regions. In Canada, this negative terms of-trade shock results in decline in consumption in the short run, but over time the expansion in productive capacity and real income results in higher levels of consumption. Real exchange rates simply depreciate in the oil-exporting regions and appreciate in the oil-consuming regions.

7 Conclusion

In this paper we have developed a five-region model of the global economy and carried out scenario analyses to study the implications of different shocks driving oil prices worldwide. The model introduces significant real rigidities in the energy sector, making both the demand and supply for crude oil extremely inelastic in the short run, thus requiring large movements in crude oil prices to clear the energy market.

Oil price shocks stemming from higher growth in the oil-importing regions are accompanied by wealth transfers through terms-of-trade movements, leading consumption to grow slower than output in the oil-importing regions. In the medium term, high investment rates in the high-growth regions crowd out investment in the oil-exporting regions. These results need not hold if higher oil prices bring about expectations of a larger availability of oil reserves in the future, prompting investment to rise in the oil-exporting countries, as the oil extraction process in the future is expected to require additional levels of capital. The positive effects of higher oil prices on consumption need not translate into reduced current account surpluses in the oil-exporting regions, to the extent that they are accompanied by an upward shift in the desired net foreign asset positions. Our conclusions about the role in increased productivity in the oil-importing regions can be reinforced by considering emerging Asia in particular, with its increased intensive use of oil in the production of its tradable goods.

We can ameliorate many of negative impacts of increasing and higher oil prices through a global tax hike on gasoline. Such a measure reduces oil prices by almost five percent, which results in a wealth transfer from oil-exporting regions to oil-importing regions. The reduction in labor tax rates raises the aggregate real wage and results in higher investment and GDP in the oil-importing regions. Consumption in the oil-importing (oil-exporting) regions increases (decreases) because lower oil prices represent a positive terms of trade shock and a wealth transfer from oil-exporting regions to oil-importing regions. On net, the world benefits from such a measure, although on a regional basis, the oil-exporting regions do not.

Going forward, a number of extensions can be suggested. First, it would be useful to develop a more detailed assessment of the role of demand and supply shocks and their

contribution to explaining the rise in oil prices over the last three years. Second, it would be useful to extend the results of FLMP (2006a) by developing a baseline scenario for the world economy, which could be used as a reference for studying the implications of alternative policies.
