

Exchange Rate and Capital –Market Regimes: Effects on Macroeconomic Performance

by

Assaf Razin and Yona Rubinstein¹

January 8, 2004

Abstract

The literature has not been able to identify clear-cut real effects of exchange-rate regimes on output growth. Similarly, no definitive view emerges from the literature in regard to the effects of open capital markets on macroeconomic performance. The paper attributes the failure of the literature to fundamental flaws, consisting of ignoring non-linearities in the effects of exchange rate and capital-market liberalization regimes, on the macroeconomic performance. The paper develops a methodology consisting of accounting for the “crisis-prone state of the economy”, summarized by a projected probability of crisis, due to sudden stops in international capital inflows. We apply the new methodology to a cross-country panel of 100 low and middle-income countries. Findings indicate that the effects of exchange rate regimes, and liberalization regimes, on macroeconomic performance go through two distinct channels: a direct channel via the real side of the economy, and an indirect channel via the financial side, which influences the probability of sudden stops. We also analyze how the projected probability of sudden stops affects the level of dollarization, and provide estimates for the effect of dollarization on growth.

¹ We thank two referees for insightful comments. We acknowledge useful discussions on the topics of the paper with Marianne Baxter, Giancarlo Corsetti, Alex Cukierman, Allan Drazen, Alejandro Izquierdo, Gian Maria Milesi-Ferretti, Ady Pauzner, and Dan Trefler. We are indebted to Gian Maria Milesi-Ferretti, Carmen Reinhart, Federico Sturzenegger, and Romain Ranciere, for providing us with various data sets. We thank Yaniv Yedid Levy for competent research assistance.

I. INTRODUCTION

The choice of macroeconomic policies is traditionally cast in terms of the well-known tri-lemma. This is a way of describing succinctly a choice among three policy goals: pegging the exchange rate, keeping the capital markets open, or conducting a business-cycle stabilizing monetary policy. The tri-lemma arises because only two of these policy goals can be achieved at any point of time. But often there is an additional policy goal: keeping the economy out of sudden stops to international capital flows, or other violent types of financial crises.² The literature, however, often ignores this aspect of the policy-regime choice problem.

We challenge two established puzzles in the international macroeconomics. The first puzzle is the failure of the literature to find any systematic difference in the macroeconomic process across exchange rate regimes. The second is the absence of any empirical relation between macroeconomic performance and capital-account liberalization. We attribute the failure of the literature to address these puzzles to a fundamental flaw. It consists of ignoring nonlinearities in the effect of exchange-rate regimes, and capital-account liberalization regimes, on macroeconomic performance. Specifically, the literature ignores a *latent* crisis state of the economy, which is summarized by an estimated probability of crisis. Our analysis focuses on the evaluation exchange rate regimes and capital-market liberalization regimes, in the presence of sudden stops.

² In fact, therefore, the policy choice problem is a Poly-lemma; rather than a Tri-lemma.

Macroeconomic theory has long recognized that there exist positive effects of the exchange rate peg regime on macroeconomic performance. The idea is that by fixing their currencies to international moneys (the Dollar, the Euro, or the Yen), fiscally-disciplined emerging economies, could rapidly accumulate exchange reserves through export growth, are able to maintain a high saving ratio, and can provide certainty to business and profit margins to investors. Such policy environment leads to a low and stable domestic rate of interest, and thus enables the economy to retain the confidence of international investors.

However, every major international economic crisis of the past 15 years (save Brazil in 2002) has been rooted in rigid exchange rate regimes. Thus, Stanley Fischer (2001) succinctly observes that: “Each of the major international capital market-related crises since 1994-- Mexico, in 1994, Thailand, Indonesia and Korea in 1997, Russia and Brazil in 1998, and Argentina and Turkey in 2000--has in some way involved a fixed or pegged exchange rate regime. At the same time, countries that did not have pegged rates--among them South Africa, Israel in 1998, Mexico in 1998, and Turkey in 1998--avoided crises of the type that afflicted emerging market countries with pegged rates.”

Indeed, there has been a long-standing view that an emerging economy under a peg, with government budget imbalances, trade deficits, and the presence of free-market policies that facilitate the outflow of capital, is likely to become vulnerable to sudden stops of capital

inflows; hence, to balance of payments crises. A “sudden stops” crisis often entails a financial or currency crisis, accompanied by a sharp fall in output.³

The idea, put forth in the present paper is that a fixed exchange rate, or open capital markets, may be good, or may be bad, for macroeconomic performance, through multiple channels: the traditional trade channel and the financial crisis channel. Therefore, a fixed exchange rate regime may be bad if it generates a big increase in the probability of sudden stop crises, to a degree that dominates the positive effect through the direct channel; and vice versa.

A related policy-evaluation issue is dollarization, and its effect on the macroeconomic performance. The “original sin” concept, introduced by Barry Eichengreen and Ricardo Hausman (1999), explain the consequences for emerging markets of abrupt departures from an exchange rate peg regimes due to sudden stops in capital inflows. The “original sin” concept underpins a crucial vulnerability of the economy under peg regimes. The phrase refers to the inability of a country to borrow abroad in its own currency, because no foreign creditor is willing to gamble on the potential exchange rate instability. A plausible explanation for the widespread use in dollarized debt is that countries are forced into this position because their monetary and fiscal policies lack credibility. If a country issued debt in domestic currency, it would have an incentive to inflate its way out of debt. Investors, who expect that the government will succumb to such temptation, refuse to buy domestic

³ For an early analytical approach to the problem of sudden stops, see Calvo (1998). Among recent papers on sudden-stops’ vulnerability, and its relation to fixed exchange rate regimes, see also Calvo (2000), Calvo, Reinhart and Vegh (1995), Chang and Velasco (2000), Ghosh, Gulde and Wolf (2000), Obstfeld and Rogoff (1995) and Williamson (2000).

currency- denominated debt papers.⁴ In net terms, the foreign currency liabilities of residents of developing and transition countries usually exceed their assets in foreign currencies, implying that they are exposed to exchange rate risk on their balance sheets, as well as through trade. Issues of both sovereign and corporate bonds on international markets are overwhelmingly in foreign currencies, even in the case of an advanced economy such as Korea, or a country whose exchange rate is strongly pegged to the U.S. dollar, such as Argentina in the 1990s.⁵

The organization of the paper is as follows. In section 2 we survey closely-related empirical literature. In section 3 we provide a discussion of a background theoretical framework, which can serve as a guide to the empirical analysis. Section 4 describes the econometric methodology. In section 5 we describe the data. Section 6 reports on the main econometric findings concerning the role of the crisis probability in the evaluations of policy regimes. Section 7 provides an empirical analysis of the dollarization channel. In Section 8 we bring

⁴ Indeed, ninety seven percent of all debt, placed in international markets between 1999 and 2001, was denominated in five currencies: the US Dollar, the Euro, the Yen, the Pound Sterling and the Swiss Franc. This feature of emerging markets' borrowing in the international market leads to balance-sheet type of currency crises, as formalized by Krugman (2000), and Schneider and Tornell (2000).

⁵ Part of this exchange rate risk can be hedged, although only (in the aggregate for a given developing country) to the limited extent that nonresidents are willing to hold local currency exposure. Large cross-holdings of foreign assets and liabilities means that the valuation channel of exchange rate adjustment has grown in importance, relative to the traditional trade balance channel. In this context, see also Lane and Milesi-Ferretti (2004), for an empirical analysis of the inter-connections between capital account openness and the exchange rate adjustment process.

domestic price crises into the empirical analysis, and perform some robustness tests, with an alternative classification of exchange rate regimes, and using a subsample of the 100 country sample. Section 9 provides a diagrammatic exposition of the fundamental non-linear effects of the exchange rate regimes, capital openness, and dollarization, based on the estimation. Section 10 describes the role played by the estimated probability of sudden stops in Argentina, Mexico and China. Finally, section 11 provides conclusions, caveats, and extensions.

II. RELATED EMPIRICAL LITERATURE

Strikingly, the empirical literature has not been able to identify clear-cut real effects of exchange-rate regimes on the open economy. Indeed, Marianne Baxter and Alan Stockman (1989) and Robert Flood and Andy Rose (1995) find that there are no significant differences in business cycles across exchange rate regimes. A recent study Frankel and Wei (2004) explores how output lost in crises is related to various controls, including the exchange rate flexibility, currency mismatch, FDI, etc. The exchange rate flexibility variable is found as not statistically significant.⁶

⁶ See however a recent study by Levy-Yeyati and Sturzenegger (2000), who find real effects of exchange-rate regime in cross-country data. Another exception is Rose (2000). In the paper, Rose uses evidence from existing currency unions in the world economy, to estimate the effect of currency unions on international trade. Rose finds that a currency union (which is an extreme form of a peg) expands bilateral trade between two average member countries by a huge proportion (200%, and more). Rose's currency union effects were reduced substantially when fixed country effects were incorporated in the analysis. Person (2001) challenged Rose's analysis, but also finds significant, albeit modest, effect of currency unions. Anderson and van Wincoop (2003) demonstrated the importance of including

(continued)

Similarly, no definitive view emerges as to the aggregate effects of capital account liberalization. Eichengreen (2001) who overviews the literature, points to ambiguities in the rather complex role played by capital account liberalizations; and Rodrik (1998) finds no significant statistical association between capital account openness and growth.⁷

III. THEORY AS A GUIDE TO EMPIRICAL ANALYSIS

Paul Krugman (2000) proposes a stylized “sudden stops” model, based on the self-fulfilling expectation equilibrium (as in sun spots equilibrium), to make sense of the number and nature of the emerging market crises of 1997-98. Credit is constrained by the borrower’s net worth, whose value is indexed to the real exchange rate, because of dollarization. The real exchange rate and aggregate investment are jointly driven by exogenous aggregate volume of exports. The model is extended in Razin and Rubinstein (2004) to fit into a class of models

country fixed effects in gravity models. Although commonly estimated gravity equations generally have a very good fit to the data, they show that they are not theoretically grounded, and prone to lead to biased estimation. They applied the method to solve the border puzzle. They find specifically that borders reduce bilateral national trade levels by plausible though substantial magnitudes.

⁷ A more definite view concerning positive effects of capital account liberalization on output, which is advanced by Fischer (1998), is supported by some evidence, provided by Quinn (1997). The role of preexisting policies, and of trade-account vs. capital-account sequencing, in determining the effects of capital control liberalization on growth and investment, is examined by Arteta, Eichengreen and Wyplosz (2001), Chinn and Ito (2002), and Tornell, Westermann, and Martinez (2004). A recent evaluation of this literature by Prasad *et al.* (2004) yields also inconclusive result. It shows no significant relationship between financial openness and growth in real per capita income across countries, even after controlling for a series of standard explanatory variables (initial income, initial schooling,

(continued)

with a unique equilibrium (i.e., with no sunspots). The extension builds on the recent global-games models (as in Morris and Shin (2000)). The extended model posits an exogenous stochastic process for the fundamentals (e.g., aggregate export volumes) that foreign creditors estimate based on public and private information. The framework features a double guessing game by the foreign creditors, who receive noisy signals. First, each foreign creditor assesses the realized state of the domestic economy fundamentals; and, second, he/she guesses the likelihood of the credit extension-withdrawal action that all the other foreign creditors are going to take, given the signals they receive. A rational-expectations equilibrium of this global game is the set of self fulfilling guesses so that the level of domestic investment implicit in the credit offers must match the actual level of investment that takes place given those offers. Importantly, the equilibrium is summarized by a *unique* projected crisis probability, directly linked to the level of aggregate domestic investment. An essential feature of the equilibrium is the existence of some thresholds in the value of some synthetic index of fundamentals (e.g., aggregate export volumes) that separate “crisis states” from “no crisis states”. Building on such global-games framework of crises implies that foreign creditors decide whether to keep lending to the country (be long on foreign currency) depending on whether their estimate of the fundamentals is above or below an endogenous equilibrium threshold. The position of the threshold depends: (a) on the distribution of the fundamentals; (b) on the stochastic features of the process through which information reaches foreign creditors; as well as (c) on the policy regime.

investment-GDP ratio, political instability, and regional dummies. See also Ariyoshi *et al*

IV. ECONOMETRIC METHODOLOGY

The dependent variable is the GDP growth rate, as an indicator of macroeconomic performance. Policy variables are modeled as dummy variables, capturing policy switches (whether a country switches from float to peg, or whether a country is imposing capital controls). These policy states of the economy are lagged to address endogeneity issues. The state of the economy is conceived as a continuous *latent* variable, capturing the strength of the exogenous fundamentals; and indicating the “crisis-prone states of nature”. When this variable moves beyond a certain threshold, there is a “crisis-prone state”. The latent variable is derived via a probit model, assessing the probability of having a crisis in the current year. The probit is specified using the same policy dummies as above, plus lagged sudden stops crises, government budget deficit, initial GDP per capita, etc. The attached Box describes the formal econometric model.

[BOX ABOUT HERE]

The main goal of this methodology is to capture the non-linear effect of policy on macroeconomic outcomes, depending on the “Crisis State” of the economy, as projected by market participants.⁸

(2000), Bhagwati (1998), Edwards (1999, 2000) and Kaplan and Rodrik (2000).

⁸ Nesting a probit estimate in a panel may raise in general issues in the distribution of the error. Often, a noisy explanatory variable may bias the standard errors in the second-stage growth regression. A bias in the standard errors exists when the latent variable, although known to the economic agent, is not known to the econometrician. This issue is mute in our case because the projected probability of the “Crisis-prone State” is the same for market participants and the econometrician. Hence, in our case the second-stage standard errors are not biased.

V. DATA

Our data set consists of 100 low-and middle-income countries (43 African countries, 26 Asian countries, 26 countries from Latin America and the Caribbean, and 5 European countries). The list of countries is shown in Table 1. The main source of data is the World Bank (World Development Indicators and Global Development Finance). The annual data ranges from 1971 to 2002.⁹ We implement a binary index based on multiple categories of the IMF- classification of exchange rate regimes, for the broad sample with the 100 countries. We also implement a binary index based on the different multiple categories of the Reinhart and Rogoff classification of exchange rate regimes, but only for a sub-sample of 58 countries of the 100 countries.¹⁰ Capital-account openness is also measured as a binary index

⁹ (We updated data set, originally assembled by Gian Maria Milesi-Ferretti and Assaf Razin (2000), to account for the Asian crisis in 1997.

¹⁰ Reinhart and Rogoff (2004) updated the IMF official classification of exchange rate regimes prior to 1997, as described in the various issues of the IMF's Annual Report on Exchange Rate Arrangements and Exchange Rate Restrictions. The IMF empirical definition of exchange rate regimes is based on formal government statements. The Reinhart-Rogoff classification is based on an empirical algorithm, factoring in ex-post behavior. Both are not pure rule-based proxies.

based of restrictions on capital account transactions, reported in the IMF Annual Report on Exchange Arrangements and Exchange Restrictions.¹¹

We measure sudden stops' crises by a large annual depreciation in the real exchange rate. In doing so we attempt to capture the effects of the crisis on the real side of the economy.^{12 13}

Evidently, unexpected fluctuations in the real exchange rate (rather than the nominal exchange rate) are more likely to have significant balance-sheet effects and other real side effects. Concretely, the sudden-stops crisis is defined by sharp changes of the real exchange rate, with a 15 percent-per-year threshold (one standard deviation in our sample).

Table 1 provides a list of countries in our broad sample. Table 2 describes the frequency of sudden-stops crises, exchange-rate regimes, and capital-account policy switches in the broad

¹¹ These are rule-based, but not quantitative measures. For alternative measures, see also Edison et al (2004).

¹² Typically in the currency crisis literature sudden stops are measured by free falls in the nominal exchange rate. However, this does not distinguish between domestic price crises and balance-of-payments crises. In our indicator, crisis episodes do not include, therefore, countries which suffer from bouts of high inflation and currency depreciation, but with a relatively stable real exchange rate, because they do not qualify to be classified as balanced-of-payments crises. Evidently, the real exchange rate measure for crisis is strongly correlated with sharp reversals in the current-account balance. See Milesi-Ferretti and Razin (2000). See also Calvo, Izquierdo and Majia (2004) on sudden stops and real exchange rate fluctuations.

¹³ Calvo, Izquierdo, and Mejia (2004) find that real exchange rate fluctuations coming hand in hand with sudden stops are a unique phenomenon in emerging-market economies. They use a sample of 32 developing countries, to analyze the empirical characteristics of sudden stops in capital flows and their relations to balance sheet effects. See also Bacchetta, Aghion and Banerjee (2001), Krugman (2000), Allen, Rosenberg, Keller, Sester, and Roubini (2002), and Eichengreen and Hausmann (1999). See also Bacchetta, Aghion and Banerjee (2001), Krugman (2000), Allen, Rosenberg, Keller, Sester, and Roubini (2002), and Eichengreen and Hausmann (1999).

sample. Overall, about 22 percent of the observations are associated with sudden-stops crises; an average of 1 percent to 4 percent of the observations indicate a float-to-peg, peg-to-float, switches to capital-controls, or switches to liberalization.

VI. MAIN EMPIRICAL FINDINGS

We now report on the estimated effects of regime switch on. We start with the effects of policy-regime switch, float to peg, peg to float, liberalization to capital controls, and capital controls to liberalization. We do so, with, and without country fixed effects. To underscore the role of the probability of sudden stops, we estimate each specification twice; that is, including and excluding the probability of a crisis. We report our findings in Table 3.

In the benchmark case where the crisis probability is absent from the growth equation, we find negligible effects of peg and liberalization policy dummies on growth; with and without fixed country effects; as expected from the traditional literature.

(i) Policy-Regime Determinants of Growth

Controlling for the crisis probability in the growth equation, in columns (I) and (iii) of Table 3, the coefficients of the policy dummies are significant in the growth equation, with and without fixed country effects. The coefficient of the crisis probability in the growth equation is negative: barely significant without country fixed effect, but highly significant with country fixed effects.

(ii) Policy-Regime Determinants of the Probability of Crisis

In the lower panel of Table 3 one can see that the probability of crises increases with a switch to peg, and falls with the imposition of capital controls; by about the same order of magnitude (almost 30 percent). Note that the coefficients of the policy dummies in the probit equation are highly significant; both with and without country fixed effects.

(iii) Reduced-Form Marginal Effect of a Switch in the Policy Regime

Observe that both the reduced-form marginal effect of a switch to peg, and the imposition of capital controls, is small.¹⁴ This is evidently consistent with the small coefficient of the policy dummy in the benchmark growth equation. This is also a typical finding in the traditional literature. In our case, however, the statement applies only to the *sample average*. Because the probit equation is non-linear and the growth equation is linear, for any country-specific and time specific cases, one effect may strictly dominates the other, or vice versa. The non-linearity is illustrated in section IX.

We now address some potential econometric issues.

A potential self-selection issue, may be stated as follows. When the crisis probability is very high, a successful switch to peg can only be implemented by countries for which governments have some strong belief about the health of domestic economic fundamentals (like the case of Hong Kong during the Asian crises). Thus, the conclusion that a switch to

¹⁴ The reduced-form marginal effect is calculated as follows. The coefficient of a policy dummy in the probit is multiplied by the coefficient of the crisis probability in the growth equation. The product is in turn added to the coefficient of the corresponding policy dummy in the growth equation.

peg is good for growth in state of very high probability of crisis may not be valid. Because it may be based on a self-selection of countries, from a pool of countries; where the same crisis probability presumably correspond to different fundamentals. This self-selection problem does not, however, arise in our case, because we control for country fixed effects. The country fixed effects effectively capture the main characteristics of health of the country domestic economic fundamentals.

Another issue is the potential endogeneity of the crisis probability in the growth equation. But, the dependency of the growth rate on crisis probability originates in effect from the country characteristics, which again are captured by the country fixed effects. These characteristics enable each country to grow either slow or fast, and at the same time to be higher or lower crisis probabilities. Because the country fixed effects are exogenous, the coefficient estimate of the crisis probability in the growth equation is unbiased.

Table 4 provides some first-look results concerning the persistency of the effect of policy regimes on macroeconomic performance.¹⁵ Accordingly, we distinguish between the effects of regime switch dummies and regime level dummies. This somewhat rough methodology aims at capturing persistent and transitory effects of policy regimes. Main findings are:

(i) Determinants of the Projected Crisis Probability

The coefficient estimates of policy regime switches, but not of the policy regime levels, are found to be significant in the probit equation. This means that the crisis probability is

¹⁵ Full-fledged dynamic analysis is not undertaken due to the fact the country characteristics do not have considerable time-variation in the data.

sensitive to changes in policy regimes but not to whether the country is under peg or float, or whether the capital account is open or not.

(ii) Determinants of GDP Growth

Controlling for the crisis probability in the growth equation, the coefficient estimates of both types of the policy regime switch, as well as the two types of the policy regime level are significant in the growth equation; albeit only in the case where country fixed effects are excluded. Once we control for country fixed effects, only the coefficient estimates of the policy regime switch are significant in the growth equation. The Durbin-Watson measure of serial correlation in our regression analysis does not significantly deviates from 2, strengthening the evidence of no level effect.

Thus, it is fair to conclude that in the broad sample of 100 countries, using the IMF classification of exchange rate regimes, we do not have good evidence for persistent effects of the policy dummies on growth.

VII. Dollarization and Sudden Stops

Different economies in our sample have also different levels of exposure to capital flow volatility, that can trigger unanticipated fluctuations in the real exchange rate.¹⁶ We use the

¹⁶ The link between dollarization and exchange rate regimes is complex, driven by several different mechanisms. Reinhart, Rogoff and Savastano (2004) find that dollarization appear to increase exchange rate pass-through. This mechanism may reinforce the claim that the

(continued)

ratio of the country's foreign currency liabilities to its money supply (FLM), as a proxy for the country's foreign currency exposure to fluctuations in the real exchange rate. We address the effect of policy-regime switch on dollarization, and the role of dollarization in the macroeconomic process.

Table 6 provides estimates of the influence of policy-regime switch on dollarization. Column (i) indicates that the policy regimes (a switch to peg, and the imposition of capital controls) do not have a direct effect on dollarization. Column (ii) indicates a significant effect of the crisis probability, as a single explanatory variable, on dollarization. Column (iii) indicates that policy regimes do not directly affect dollarization, and the crisis probability significantly explain the dollarization, in a regression where both policy regime switch dummies and the crisis probability are included.

This means that the influence of policy regimes on dollarization is indirect: it comes through their effect on the crisis probability (recall that a switch to a peg raises and imposition of capital controls reduces the probability; see Table 3).

We now analyze how dollarization (measured by FLM) affects growth. Column (i) and (ii) of Table 7 indicate that FLM does not have any direct influence on growth, once we control

“fear of floating” is a greater problem for highly dollarized developing economies. The role of balance sheet effects, the linkage between currency risk and country risk, and the impact of dollarization on trade are analyzed in Levy Yeyati and Sturzenegger (2003). See also Calvo and Reinhart (2000).

for the actual realization of sudden stops' crisis. The crisis, as expected, reduces growth, and in a significant way. In column (iii) of Table 7 we add an *interaction* term, between dollarization and (realized) sudden stops. The coefficient of the interaction term is negative and highly significant. This means that, although dollarization does not have an independent influence on growth, the interaction between dollarization and the *actual* crisis, tend to reduce the growth rate drastically.

This means that the following policy-regime induced mechanism may have been at work in the sample. The imposition of capital controls tend to lower the *probability* of sudden stops; and the decrease in the *probability* of sudden stops, in turn, tend to raise the level of dollarization. If a crisis *actually* occurs, then the growth rate diminished. If, however the crisis does not materialize, then growth is unaffected.

VIII. Domestic Price Crises and Robustness Tests

The literature has been dealing extensively with the relation between inflation and growth. Bruno and Easterly (1998) propose a method, based on discrete high inflation crises, to look at the relationships between inflation and growth. They find that growth falls sharply during discrete high inflation crises; then growth recovers quickly after inflation falls below the threshold. Their approach, however, implies that growth is negatively affected by high inflation, above a certain threshold; but growth is not affected by inflation below the the

threshold. This discontinuity appears to be somewhat arbitrary. The Bruno-Easterly methodology is based on *actual* domestic price crises. Our methodology points out to the role of a latent and *continuous* “crisis-prone state”, estimated by a continuous crisis probability function. This means the even if the crisis does not materializes, still the crisis probability could be sufficiently big to affect the rate of growth. In this section we consider the effect of domestic price crises in addition to sudden stops’ crises.

As regard to exchange rate regimes, we switch, in this section, to the Reinhart-Rogoff classification. The alternative classification applies to only a subset of the original sample of 100 countries. Accordingly, we perform in this section a variety of robustness tests: sample-robustness, and regression-specification. Table 8 describes the frequency of currency and price crises in the sub-sample. Sudden stops’ episodes appear in 65.5 percent of observations, whereas domestic-price-crisis episodes occur in 46.1 percent of the observations. Table 9 describes the frequency of switches to peg, and switches to float in the sub-sample. Both types of policy-regime switch occur in about 10 percent of the total of the sub-sample observations.

We investigate domestic price crises factor into the analysis of the preceding sections. In Column (i) in Table 10 (using the Reinhart-Rogoff classification in the sub sample), is analogous to column (iv) in Table 3 (using the IMF classification in the broad sample of 100 countries). Qualitatively, the findings are similar: a switch to peg has positive coefficient, a switch to capital controls has a negative coefficient, and the crisis probability has a negative

coefficient; all estimators are statistically significant. This can serve as evidence for the robustness of our methodological approach.

In column (ii) of Table 10, the sudden stops' probability includes the effect of the domestic price crisis. Notice that the effect of the crisis probability on growth is barely significant. In column (iii) we include two types of a projected probability of sudden stops: one which includes, and the other which excludes, the effect of the price crisis. Observe that the coefficient of the latter type of projected probability is highly significant and negative. The estimate is larger in absolute value than the corresponding coefficient in column (i), Table 10. The coefficient of projected probability of sudden stops which includes the effect of price crisis, in column (iii), is however not significant. We interpret this as evidence that domestic price crisis affect growth through the sudden-stops probability channel.

IX. THE FUNDAMENTAL NON-LINEARITIES

Recall that to find any systematic difference in the macroeconomic process across exchange rate regimes, the analysis has to account for *non-linearities* in the effect of balance-of-payments policy regimes on growth.

The reduced-form marginal effect of a policy-regime switch from float to peg, which incorporates both a direct and an indirect effects (which is working through the crisis probability), is plotted in Figures 1, against the projected probability. The U-shaped graph implies that in the extreme ranges, when the probability is relatively low and when the

probability is relatively high, the marginal effect of the policy switch is positive. Because in these ranges of the projected probability function the regime switch does not trigger a big change in the probability, and the direct effect on growth of the regime switch dominates the indirect effect. In the intermediate range for the probability function, the reduced-form marginal effect of a policy-regime switch from float to peg is negative. Because the policy-regime switch does not generate a big marginal increase in the probability, and the indirect effect of the regime switch dominates the direct effect. Similarly, Figure 2 demonstrates how the reduced-form marginal effect of a switch from capital controls to capital-account liberalization, which incorporates both the direct and the indirect effects, depends on the crisis probability. The U-shaped diagram implies that the marginal effect of the policy switch is positive, in the extreme ranges of the projected probability function. In contrast, in the intermediate range the marginal effect of the policy-regime is negative, because the crisis probability is very sensitive to the policy-regime switch. Figure 3 plots the reduced-form marginal growth effect of the regime switch to peg against the probability of sudden stops; with and without the imposition of capital controls. Notice capital controls transformed the U-shaped curve to downward sloping curve; except for small values of the crisis probability. Figure 4 plots the reduced-form marginal growth effect of the switch to peg, against the crisis probability, for two levels of dollarization ($FLM = 0.75$ and $FLM = 0.1$). With smaller dollarization, the U-shaped curve is flatter than with large dollarization, indicating the dampening effect of dollarization on the probability of crisis.

V. POLICY REGIMES AND SUDDEN STOPS: ARGENTINA, CHINA, AND MEXICO

Based on our estimates in Table 3, and the country-specific characteristics, we plot in Figure 5 the projected probability of sudden stops, and the degree of dollarization for Argentina, China, and Mexico. These countries have different histories concerning the exchange rate regime, and capital-account openness, and sudden stops.

We first provide a brief refresher to highlight unique developments in these economies. The Argentina crisis of 2000-2 was among the most severe of recent currency crises. With the economy in a third year of recession, in December 2001, Argentina defaulted on its sovereign debt, and in early January 2002, the government abandoned the convertibility regime, under which the Peso was pegged with the US dollar since 1991. The convertibility regime was also part of a broader agenda of market-oriented structural reforms, including liberalizing the capital account transactions. The devastating crisis could have been to some extent anticipated, as could be seen in Figure 5, given the level of dollarization and projected probability of sudden stops before the actual crisis took place.¹⁷

¹⁷ Under the Convertibility Plan, Argentina saw marked improvement in its economic performance, during the early years. Inflation, which averaged 27 percent a month, declined to annual single digits, and remained low. The collapse of hyperinflation put downward pressure on the probability of sudden stops. Growth was solid through early 1998 (except for brief period of setback associated with the Mexican crisis) and averaged 6 percent during 1991-1998. The probability of crisis has increased and Argentina moved into recession due to

(continued)

The Mexican economy fell into one of the worse crises it has experienced in 1994, a year after the NAFTA pact. The crisis erupted because Mexico's growing trade deficit was financed by foreign investment. The rules included in NAFTA made Mexico more vulnerable than ever to the exodus of speculative capital. In 1996, GDP per capita was 8% lower than in 1981, the last year of real growth before the 1982 debt crisis.

In contrast to Argentina, and Mexico, most of China's growth over the past quarter-century can be explained by high rates of investment and the movement of workers from the low productivity rural periphery to the high productivity urban centers. China also built good infrastructure, an educated work force, and high rate of savings. China gradually liberalized its trade to join the WTO, but did not liberalize its capital markets, to the degree that Argentina has done in the early 1990s when it pegged it employed a hard peg policy.¹⁸

the sustained appreciation of the US dollar, and the devaluation of the Brazilian real in 1999.

Deflation and output contraction set in, without a simple exit strategy from the hard peg straight jacket.

¹⁸ It is argued that the main constraint on China's growth is its financial system's inability to allocate capital efficiently, with the associated risk of bad loans in the banking system and the barriers to capital inflows from abroad. The China growth performance fits our main hypothesis that, on one hand, capital controls are bad for growth; but on the other hand, because they reduce the probability of capital flow reversals and speculative attacks, they are also good for growth. More recently, Michael Dooley, David Folkerts-Landau and Peter Garber (2004) argue that China, and other Asian countries can easily finance the US current account deficit for another decade. In the present arrangement, which looks like a revived Bretton Woods, the US is at the center of the system, while China and other Asian countries are in the periphery, replaced the old periphery which consisted of Europe and Japan. The old periphery supported undervalued currencies by capital controls and the purchase of dollar reserves, to rebuild their economies after war world II. Recently, in the new periphery China and other Asian countries have been pegging their currencies to the dollar at artificially low

(continued)

Figure 6-8 demonstrates the contrasting policy regimes across the three countries, and the close association between dollarization, the exchange rate regime and sudden stops' crises.

VI. CONCLUSION

Our estimation implies that the overall effect of balance-of-payments regimes on macroeconomic performance work through the crisis probability channel, which is intrinsically non-linear. There are ranges for the set of the main explanatory variables, for which the effect of the policy regime on the likelihood of a crisis is substantial; whereas in other ranges the effect is unimportant. The reduced-form marginal effect of a policy-regime switch on growth depends on the magnitude of the probability of sudden stops crisis, and on the degree of dollarization. This means the exogenous country-specific shocks in the sample period imply that policy-makers faced different choices as regard to the desired exchange-rate and capital-account liberalization regimes.

We list a few caveats.

rates, in order to keep their exports competitive, so as to create jobs for their vast pool of underemployed workers. Governments with large dollar reserves, such as China, are concerned about both keeping the dollar from depreciating and ensuring that US treasury bond interest rates do not go up. Given that international reserves are huge, \$500bn in China, the potential loss is big. A 10 percent appreciation of the renminbi means a capital loss in real terms (if domestic inflation is unaffected) of \$50bn for the Chinese Authorities. Assuming the average duration of bond portfolios 4 years, a 2 percent increase in the US interest rate means another \$40 bn loss. Thus, China is somewhat "trapped" in the US dollar peg.

The data have little time variability concerning the country- specific characteristics, which does not enable a full-fledged dynamic analysis. Accordingly, the econometric methodology is essentially static.

The background theory posits that optimizing agents will design their portfolio strategies based on expectations about policy rules. It is not necessary that a switch from float to peg have the same meaning in different policy and institutional environments. On the other hand, policy rules may be endogenous in an environment vulnerable to sudden stops.

To take care of the issue of the endogeneity of policy regimes we had to resort to the second-best method of lagged policy dummies because we did not have access to more powerful instruments.

Indicators of capital controls used in the analysis do not distinguish controls on inflows and outflows. These two types of controls may have quite different effects on capital inflows, and therefore on the probability of sudden stops.

The IMF empirical definition of exchange rate regimes is based on formal government statements. The Reinhart-Rogoff classification is based on an empirical algorithm, clustering ex-post behavior. Both are not pure rule-based proxies, as our framework assumes.

We conclude with two extensions.

It has been a well discussed view that openness to trade makes countries less vulnerable to sudden stops. Rose (2002) argues that threatened penalty of lost trade is the answer to the puzzle “why do countries seldom default on their international debt?”. He offers empirical evidence that strong trade links are correlated with low default probabilities. But strong trade links are expected also to correlate with growth rates. Thus trade openness may have two reinforcing effects on growth: a direct effect on the growth process, and an indirect effect

growth through the probability of sudden stops. A useful extension is to apply our methodology also to international - trade regimes.

Another extension is to consider also the choice between monetary policy rules. Different rules influence the probability of bank runs (as in Diamond and Diving (1983)), and the probability of stock market crashes, in different ways. Proper evaluation of the desirability of monetary rules can incorporate the effect of these rules on the probability of financial crises; similar to our analysis of the evaluation of balance of payments regimes.

Box: The Statistical Model

Let $Y_{1,j,t}$ denote the growth rate of country j in time t as measured in terms of GDP per capita. Let $Y_{2,j,t}^*$ denote a *latent* variable indicating the crisis prone state of the economy. That is, if $Y_{2,j,t}^* \geq 0$, a sudden stop crisis occurs, whereas if $Y_{2,j,t}^* < 0$, a sudden stop crisis does not occur. That is:

$$Y_{2,j,t} = \begin{cases} 1 & \text{if } Y_{2,j,t}^* \geq 0 \\ 0 & \text{otherwise} \end{cases}, \quad (1)$$

where, $Y_{2,j,t}$ is a binary variable, which equals 1 if sudden stop crisis occurs in country j at time t , and 0 otherwise.

Consider two policies: (i) a float-peg policy and (ii) a liberalization-controls policy. To simplify, assume that a policy is binary. Denote by D_1 the float-peg policy and by D_2 the liberalization-controls policy:

$$D_{1,j,t} = \begin{cases} 1 & \text{if peg} \\ 0 & \text{if float} \end{cases}, \quad (2)$$

and:

$$D_{2,j,t} = \begin{cases} 1 & \text{if capital controls} \\ 0 & \text{if liberalization} \end{cases}. \quad (3)$$

To simplify let us assume that both $Y_{1,j,t}$ and $Y_{2,j,t}^*$ can be expressed as a *linear* function of policy variables (D_1, D_2), standard controls (X). The growth equation is as follows.

$$Y_{1,j,t} = \beta_1 X_{j,t} + \gamma_1 D_{1,j,t} + \delta_1 D_{2,j,t} + \phi_1 \hat{Y}_{2,j,t}^* + \varepsilon_{1,j,t}, \quad (4)$$

where, $\varepsilon_{1,j,t}$ is a country specific time variant *i.i.d.* random shock and $\hat{Y}_{2,j,t}^*$ is the best predictor by the market participants of $Y_{2,j,t}^*$. Similarly the latent variable equation is a linear function of policy variables (D_1, D_2) and standard controls (Z):

$$Y_{2,j,t}^* = \beta_2 Z_{j,t} + \gamma_2 D_{1,j,t} + \delta_2 D_{2,j,t} + \phi_2 Y_{1,j,t} + \varepsilon_{2,j,t}, \quad (5)$$

where, $\varepsilon_{2,j,t}$ is a country specific time variant *i.i.d.* random shock. Latent variables are common in econometric analysis. Usually the adjective *latent* means that the variable is by unobserved by the econometrician but it is known to the decision makers. This is not however the case here. Both the econometrician and market participants do not observe the "true" $Y_{2,j,t}^*$. Both assume that the right hand side of Equation (5) determines $Y_{2,j,t}^*$.

Let $P_{j,t}$ be the conditional probability that country j will face currency crisis in period t , that is $P_{j,t} = \Pr(Y_{2,j,t} = 1 \mid \cdot)$. Given our assumption,

$$P_{j,t} = \Pr(\beta_2 Z_{j,t} + \gamma_2 D_{1,j,t} + \delta_2 D_{2,j,t} + \phi_2 Y_{1,j,t} > -\varepsilon_{2,j,t}) \quad (6)$$

Assuming that $\varepsilon_{2,j,t} \sim N(0, 1)$ then:

$$P_{j,t} = \Phi(\beta_2 Z_{j,t} + \gamma_2 D_{1,j,t} + \delta_2 D_{2,j,t} + \phi_2 Y_{1,j,t}) \quad (7)$$

where Φ is the cdf of the unit normal distribution (above).

Note that we can identify the parameters of the "crisis-selection" equation by estimating the Probit equation (8), where the projected likelihood is:

$$\hat{P}_{j,t} = \Phi \left(\hat{\beta} Z_{j,t} + \hat{\gamma}_2 D_{1,j,t} + \hat{\delta}_2 D_{1,j,t} + \hat{\phi}_2 Y_{1,j,t} \right) \quad (8)$$

Assuming momentarily that policy is exogenous. Typically, policy action is endogenous. Thus obviously we cannot identify the parameters of interest using the OLS estimators for equations (4) and (5). Therefore, we use lag variables to instrument policy variables $D_{1,j,t}$ and $D_{2,j,t}$. We could recover the parameters of interest in the growth equation by estimating the following equation:

$$Y_{1,j,t} = \beta_1 X_{j,t} + \gamma_1 D_{1,j,t} + \delta_1 D_{2,j,t} + \phi_1 \Phi^{-1} \left(\hat{Y}_{2,j,t}^* \right) + \varepsilon_{1,j,t}, \quad (9)$$

Equation (9) provides consistent estimates for the parameters of interest both for the econometrician and the market participants. It is worth noticing that the term $\Phi^{-1} \left(\hat{Y}_{2,j,t}^* \right)$ is not a first stage estimate of what is being used by market participants, but rather the actual variable they use in their decisions. This is in contrast with the case when the decision makers *observe* the *latent* variable but the econometrician *does not*. In this case, assuming we have the correct model and that both the econometrician as well as market participants share the same set of data, the variable is not an econometric proxy for the correct variable, and therefore we do not need to correct the standard errors in the 2nd stage of the regression.

Table 1:
The Frequency of Crises, Switches Between Float and Peg and
Switches between Capital Controls and Liberalizations (%)

Variable	Frequency
Crsises	22.61
Switches to peg	1.71
Switches to float	3.91
Switches to controls	1.03

**Table 8:
The Frequency of Sudden Stop and Domestic Prices Crises
Using Reinhart-Rogoff (2004) Classification*, ****

		<u>Domestic Price Crises</u>		
		<u>0</u>	<u>1</u>	
Sudden Stops Crises	0	24.6	9.9	34.5
	1	29.3	36.3	65.5
		53.9	46.1	100.0

Notes:

* Reinhart and Rogoff (2002) classified into 5 categories: (i) peg, (ii) limited flexibility, (iii) managed floating, (iv) freely floating and (v) freely falling. We aggregate it into 2 main categories: (i) peg_rr, including the first 3 and (ii) float_rr, including the other two.

** Data includes 58 countries in the years 1970 to 1997

Domestic prices crisis = 1 if the inflation rate is above 20% per year and 0 otherwise.

Sudden stop crisis = 1 if the real exchange rate depreciation is above 15% per year and 0 otherwise.

**Table 9:
Switches Between Float and Peg
Using Reinhart-Rogoff (2004) Classification*, ****

Variable	Frequency
Switches to peg	10.18
Switches to float	9.97

Notes:

* Reinhart and Rogoff (2002) classified into 5 categories: (i) peg, (ii) limited flexibility, (iii) managed floating, (iv) freely floating and (v) freely falling. We aggregate it into 2 main categories: (i) peg_rr, including the first 3 and (ii) float_rr, including the other two.

** Data includes 58 countries in the years 1970 to 1997

Table 10:
Exchange Regime and Capital Controls
Using Reinhart-Rogoff (2004) Classification*,**
Fixed-Effects Estimators

Dependent Variable: Growth Rates

Variables	(i)	(ii)	(iii)
Peg at time t-1	1.656 (0.557)	1.330 (0.549)	1.729 (0.565)
Capital Controls at t-1	-0.439 (0.890)	-0.587 (0.991)	0.156 (1.022)
Switching to Capital Controls between t-2 to t-1	-5.852 (1.799)	-3.374 (1.518)	-6.155 (1.809)
The probability of having currency crisis this year [^] excluding the effect of price crisis	-14.843 (4.937)		-22.359 (7.996)
The probability of having currency crisis this year - real [^] including the effect of price crisis		-6.824 (4.084)	7.632 (6.578)
<u>Controllers</u>			
Growth rate at time t-1	0.176 (0.034)	0.191 (0.034)	0.183 (0.034)
Growth rate at time t-2	0.008 (0.035)	0.022 (0.035)	0.019 (0.035)
Currency crisis at time t-1	2.812 (0.978)	0.917 (0.629)	3.340 (1.069)
Currency crisis at time t-2	-1.904 (0.479)	-1.804 (0.483)	-1.831 (0.481)
Price (CPI) crisis at time t-1	-0.100 (0.491)	1.078 (0.772)	-1.251 (1.133)
Price (CPI) crisis at time t-2	0.385 (0.488)	0.374 (0.491)	0.468 (0.490)

Notes:

* Reinhart and Rogoff (2002) classified into 5 categories: (i) peg, (ii) limited flexibility, (iii) managed floating, (iv) freely floating and (v) freely falling. We aggregate it into 2 main categories: (i) peg_rr, including the first 3 and (ii) float_rr, including the other two.

** Data includes 58 countries in the years 1970 to 1997

[^] The estimated the likelihood for a currency crisis ignoring the effect of price crisis.

[^] The estimated probability for a currency crisis including the effect of past price crisis

All specifications include linear time trend
